ABSTRACT

Blue carbon stock of the seagrass meadows of Gulf of Mannar and Palk Bay, off Coromandel Coast, south India, were computed from the organic carbon content and dry bulk densities of sediment core taken from the seagrass meadows of these two ecosystems. The Gulf of Mannar (GoM) and Palk Bay (PB) harbour 13 seagrass species dominated by Cymodocea serrulata and Syringodium isoetifolium. The soil carbon density of both GoM and PB were higher in subsurface cores. The blue carbon stock of seagrass meadows of the GoM was estimated as 0.001782 Tg and that of PB as 0.043996 Tg. The estimated value of blue carbon stored in seagrass meadows of GoM was 17820 US$ and that of PB was 43,99,682 US$. The results of this study are discussed in the light of climate change mitigation, emphasising the need to conserve these underwater meadows.

Keywords: Blue carbon sink, Climate change, Coromandel Coast, Organic carbon, Seagrass meadows

Ecosystems capable of absorbing and storing large amounts of carbon dioxide are known as carbon sinks and the term blue carbon refers to the carbon stored in sediments from coastal ecosystems such as seagrass meadows, mangrove forests and salt marshes. Coastal ecosystems become more relevant for carbon sink as two-third of the earth’s surface is covered by seawater. Seagrass meadows are among the most important coastal marine ecosystems for long term carbon storage and conditioning of coastal waters. Seagrasses sequester atmospheric CO₂ through photosynthesis and deposit in the sediment. Though seagrass meadows occupy less than 0.2% of the area of the world’s oceans, they are estimated to bury 27.4 Tg C yr⁻¹ (1 Terra gram = 1 x 10¹² kg) which is roughly equivalent to 10% of the yearly estimated organic carbon (C org) burial in the oceans (Duarte et al., 2005; Fourqurean et al., 2012). Because of this great potential, good management of seagrass ecosystems assign higher importance for countries to make progress in meeting their target of sustainable development goal 14 (SDG-14) set by the Paris Agreement (UNDESA, 2020).

Detailed review of goods and services offered by seagrass meadows can be gleaned from the works of Terrados and Borum (2004) and Unsworth and Unsworth (2013). The seagrass meadows are known to serve as antacid to contain ocean acidification as they can sequester dissolved CO₂ and enrich the lagoon with oxygen through canopy photosynthesis and storage of blue carbon (12%) in their underground shoot and root systems. Banerjee et al. (2018) studied a combined air-water flux of CO₂ and CH₄ from the seagrass meadows of brackishwater Chilika Lake. Growing coastal populations and increasing coastal developments threaten seagrass habitats globally and the decline of seagrass meadows is taking place very rapidly (Waycott et al., 2009; Fourqurean et al., 2012; Kaladharan and Anasukoya, 2019). It is proved with experimental evidence that restoration of seagrass habitat could enhance carbon sequestration in the coastal zone (Greiner et al., 2013). Gulf of Mannar and Palk Bay, off south-east coast of India, harbour 13 species of seagrass plants dominated by Cymodocea serrulata and Syringodium isoetifolium and the seagrass meadows of these regions are constantly undergoing tremendous anthropic pressures causing considerable reduction in seagrass density and coverage (Kannan et al., 1999; Susila et al., 2012; Thangaradjou and Bhatt, 2018). Blue carbon stock of Gulf of Mannar (GoM) and the Palk Bay (PB) were computed according
to the procedure mentioned in Jones et al. (2005), from the soil carbon density of sediment core samples taken from 14 sites within the Gulf of Mannar and 18 sites within Palk Bay regions, off the Coromandel Coast, southern India, during August-October 2019 (Fig. 1). Sediment samples up to 20 cm depth were taken in triplicate from each site using a locally fabricated sediment corer (Fig. 2), 1 m long having 5 cm lumen dia, to get two cores of 10 cm interval. Hence from each site, 6 sediment cores [3 nos. of Core A (surface core), 0-10 cm and 3 nos. of Core B (subsurface core), 10-20 cm] were obtained. After determining the dry weight and dry bulk density of the cores, organic carbon content \((\text{C org} \%)\) in the sediment cores were determined according to the standard method of Walkley and Black (1934). Area of seagrass cover in the GoM was obtained from Susila et al. (2012) and that of PB from Tangaradjou et al. (2015).

UNESCO describes the Gulf of Mannar Biosphere Reserve (GoMBR) as one of the world’s richest region in marine biodiversity having 4223 species of plants and animals making it “one of the richest coastal regions” in India (UNESCO.ORG). Seagrass, growing as underwater meadows are considered ecosystem engineers due to their higher primary production, carbon and nitrogen.

Fig. 1. Map of the study area showing sampling sites in Gulf of Mannar and Palk Bay (Sourced from Google Earth)

Fig. 2. Locally fabricated corer used for sediment collection
sequestration potential and long term storage of carbon in sediment. The nature of sediment in GoM region except for Valinokkam area was generally coarse to fine sandy while that of PB was fine sand to clayey. The organic carbon content (C \text{org}) in the sediment cores of GoM region showed a mean value of 0.0965±0.014%, ranging from 0.0286-0.2821% in core A (0-10 cm). The mean value was 0.0878±0.022%, ranging from 0.0286-0.2413% in the subsurface core B (10-20 cm). In the Palk Bay region, a higher mean of 0.7147±0.081% ranging from 0.2342-1.297% was observed in core B, while the surface core A registered a mean of 0.6607±0.105% ranging from 0.2342-1.574%. The soil carbon density of coastal sediments along the Palk Bay was found to be higher than that of GoM region (Tables 1 and 2). The reason for the increase in PB is presumed to be due to higher settlement of seagrass leaf litter and organic matter in the bay regions besides the wider area of seagrass cover. Blue carbon stock of seagrass meadows of PB was quantified as 0.001782 Tg C and that of GoM was estimated to be 0.043996 Tg C (Table 3).

Our results are comparable with the available reports (Duarte et al., 2010; Lavery et al., 2013) who opined that for a seagrass area of 300,000 km\(^2\), the net community production of seagrass meadows would range from 20.7 to 50.69 Tg C yr\(^{-1}\). From Rottnest Island, Australia, Bedulli et al. (2020) derived carbon stocks of 5.1±0.7 kg C org m\(^2\) in 0.5 m thick seagrass soil deposits. Seagrasses of Red Sea seagrass meadows are known to store 3.4±0.3 kg C org m\(^2\) in 1 m thick soil deposit which accumulate at the rate of 6.8±1.7 g C org m\(^2\) yr\(^{-1}\) (Serrano et al., 2018). According to Serrano et al. (2019) the price of blue carbon is fixed at 10 US$ and hence the blue carbon stored in the seagrass meadows of GoM and PB could be valued at 17820 US$ and 4399682 US$, respectively.

Even the mildest rate of depletion in seagrass cover can cause the emission of blue carbon from the sink back to the atmosphere. Restoration of habitats for Zostera marina for more than 1700 ha in the coastal bays of Virginia as a model system increased the carbon storage in the coastal sediments considerably (Greiner et al., 2013). Hence the outcome of this study is relevant in the light of climate change.
change mitigation and emphasises the need to conserve these underwater meadows from further deterioration. This study provides baseline quantitative data on blue carbon stock of seagrass meadows of Gulf of Mannar and Palk Bay and the annual increment of carbon being sequestered by seagrass meadows can be inferred from future assessments in the years to come. Any fluctuation from this base value during subsequent observations can indicate the status of health of these fragile ecosystems.
